Intraoperative aerosol box use: does an educational visual aid reduce contamination?

Running Title: Visual aid and aerosol box use
Abstract

Background: The aerosol box was rapidly developed and disseminated to minimize viral exposure during aerosolising procedures during the COVID-19 pandemic, yet users may not understand how to use and clean the device. This could potentially lead to increased viral exposure to subsequent patients and practitioners. We evaluated intraoperative contamination and aerosol box decontamination and the impact of a preoperative educational visual aid.

Methods: Using a double-blinded randomized design, forty-four anesthesiology trainees and faculty completed a simulated anesthetic case using an aerosol box contaminated with a fluorescent marker; half of the subjects received a visual aid prior to the simulation. Intraoperative contamination was evaluated at 10 standardized locations using an ultraviolet light. Next, subjects were instructed to clean the aerosol box for use on the next patient. Following cleaning, the box was evaluated for decontamination using an ultraviolet light.

Results: Median total contamination score was significantly reduced in the experimental group (5.0 vs 10.0, p<0.001). The aerosol box was completely cleaned by 36.4% of subjects in the experimental group compared to 4.5% in the control group (p = .009).

Conclusions: The use of a visual aid significantly decreased intraoperative contamination and improved box cleaning. Despite these findings, a potentially clinically significant amount of viral exposure may exist. Thorough evaluation of the risks and benefits of the aerosol box should be
completed prior to use. If an aerosol box is used, a visual aid should be considered to remind practitioners how to best use and clean the box.

Introduction

The coronavirus disease (COVID-19) pandemic has led to numerous developments in personal protective equipment (PPE) as a means to protect healthcare workers from SARS-CoV-2, the virus responsible for COVID-19 [1,2]. Respiratory failure associated with COVID-19 often necessitates tracheal intubation, a high risk procedure exposing healthcare workers to droplet and aerosol particles carrying a significant viral load [3–5].

One potential exposure mitigation strategy is the use of a barrier device, such as a clear plastic aerosol box, over the patient’s head to contain any aerosols or droplets [6,7]. Early in the pandemic, news outlets and social media rapidly disseminated the construction and use of these aerosol boxes [8] and numerous variations on this basic design exist [9–11].

Simulation studies have demonstrated the effectiveness of aerosol boxes in preventing droplet spread [12–14], but concerns exist regarding clinical effectiveness in aerosol prevention and possible unintended complications with their use [8,15–18]. Due to the rapid development and dissemination of this medical device, no formal instructions or guidelines for use exist. Users may not know how to appropriately use and decontaminate the aerosol box, which may lead to the box itself becoming a vector for viral transmission between patients or practitioners. Furthermore, the simple design may lead users to believe they know how to use the device even though they may not. Because medical devices should include instructions for proper use and this device lacks any such
instructions, the authors postulate that an educational visual aid for proper aerosol box use may lead to safer utilization of the aerosol box.

In this study, we aim to evaluate the potential for viral particle spread using a fluorescent marker during a simulated anesthetic utilizing an aerosol box. Specifically, we have included an educational visual aid, containing a targeted list of recommendations describing best practices for the use and cleaning of this novel medical device [19–21]. Our primary endpoint was decreased intraoperative contamination of the anesthesia work area, while our secondary endpoint was improved decontamination of the aerosol box following use.
Materials and Methods

This study received an exemption from written consent by our institutional review board. Anesthesiology trainees and faculty were voluntarily recruited to participate in this prospective, double-blinded, randomized-controlled study. Randomization was completed using a computer-generated randomization program. The study was completed in the Mount Sinai Department of Anesthesiology HELPS Simulation Center.

Each subject was randomized to an experimental group and received a visual aid describing how to use an aerosol box (figure 1, supplemental materials), or to a control group without a visual aid. The visual aid content was developed using World Health Organization recommendations [19] as well as anesthesiology-specific guidelines [20,21] for infection control and intubation during the COVID-19 pandemic.

One study member not involved in data collection provided the subject with a simulation prompt describing a patient under investigation for COVID-19 undergoing a laparoscopic appendectomy and the visual aid, if appropriate. The subject then had the opportunity to practice intubating a mannequin with an aerosol box in place, using a video laryngoscope (GlideScope™, Verathon Inc., Bothell, WA, USA); each subject was provided with sufficient time until they felt comfortable. The subjects were then brought into another room for the simulation. The visual aid was left in the previous room in order to keep the remaining study members blinded to their
The aerosol box was created using the initial widely publicized design specifications [6] and constructed using clear acrylic plastic and rubber cement. The aerosol box was then placed over an airway management trainer (Laerdal, Stavanger, Norway). An ultraviolet fluorescent marker (Glo-germ™, Glo-Germ Company, Moab, UT, USA) was used in a lotion and powder form. One mL of the lotion was placed on the task trainer’s lips and inside the mouth to simulate oral secretions, while ⅛ teaspoon of powder was distributed uniformly within the inside of the aerosol box using a powder brush, to simulate droplet contamination (figure 2). The fluorescent marker is not fluorescent under normal lighting conditions and was minimally visible during the simulation.

A standardized simulation sequence was utilized (supplemental materials). Vital signs were generated using a high-fidelity patient simulator (CAE human patient simulator, Saint-Laurent, Quebec, Canada). Subjects were instructed to wear standard PPE for patients under investigation for COVID-19, including a gown, gloves and surgical mask according to our local protocols. In order to conserve PPE, N95 respirators, masks, eye protection and head coverings were not used in the study. Each subject then induced anesthesia and intubated the task trainer with a video laryngoscope with the aerosol box in place. Subjects were required to administer drugs using saline filled syringes through a stopcock on the intravenous line. Additional relaxation was requested by the simulated surgeon prior to incision, in order to prompt additional medications to be
administered through the intravenous line. Upon completion of the simulated surgery, the subject then prepared for and performed extubation of the task trainer.

Upon completion of the simulation, 10 standardized sites (table 1) were evaluated for viral contamination using an ultraviolet (UV) light by two study members who were blinded to subject randomization. These sites were selected based on previous intraoperative contamination studies [22–24]. Sites were deemed clean if no fluorescence was observed (0) or contaminated if any amount of fluorescence was visualized (1). The primary outcome was determined to be a total contamination score with a maximum score of 10. Subjects waited in the adjacent room while contamination scoring took place. Additionally, a secondary outcome was individual sites of contamination.

Finally, subjects were then instructed to clean the aerosol box in order for it to be used for their next patient. Cleaning wipes capable of cleaning the fluorescent marker (PDI Sani-Cloth, Woodcliff, NJ, USA) were provided and subjects were able to clean the box until they were satisfied with its cleanliness. Two study members blinded to subject randomization then examined the box under a UV light for areas not cleaned by the cleaning wipe. A scoring system was developed using a numbering system as follows: 1 = completely clean, 2 = 1-2 areas missed, 3 = 3-4 areas missed and 4 = 5 or more areas missed. Box cleaning scores were evaluated as a secondary endpoint.
Between simulations, all surfaces in the simulation lab were fully cleaned, as confirmed by two members of the study team using a UV light. Any materials which could not be fully cleaned were discarded and replaced.

Statistical Analysis

Prior to the beginning of the study, pilot simulations without the educational visual aid had a median contamination score 8.0 [Interquartile Range 7.0-9.0]. We predicted the educational visual aid would decrease contamination score would be decreased by 50% to a median contamination score of 4.0. Using an $\alpha$ of 0.05 and a $\beta$ of 0.2 and the predicted 50% decrease in contamination score, it was determined that a sample size of 22 subjects in each group would be needed for sufficient power. In order to allow for potential dropout, we aimed to recruit 24 subjects per group in order to reach our targeted sample size, though no subjects dropped out and we were able to achieve a full sample of 22 subjects per group. All continuous variables were first assessed for normality via Shapiro-Wilk or Kolmogorov–Smirnov tests, where applicable as well as visual inspections of histograms. All continuous variables were found to be non-normal and are reported as median [Interquartile Range]. Proportions are reported as n (%). For categorical variables, chi-square tests were utilized, unless one value in the 2x2 matrix was under 5, in which case Fischer’s exact test was utilized. For binary tests, odds ratios with 95% confidence intervals are reported. For continuous non-normally distributed variables, Mann-Whitney U test was used, with
differences between groups and 95% confidence intervals estimated via Hodges-Lehman estimation.

All calculations were performed via SPSS Statistics Version 24 (IBM, Aramonk, NY, USA).
Results

Forty-four subjects were enrolled in the study with 22 subjects in each group (figure 3). The control group consisted of 16 trainees and 6 faculty members, while the experimental group consisted of 14 trainees and 8 faculty members. All subjects completed the study.

Our primary endpoint, median total contamination score, was 10.0 [IQR 8.0-10.0] for the control group and 5.0 [IQR 4.0-8.25] for the experimental group. Total contamination score was found to be significantly reduced in the experimental group (p<0.001). When evaluating only trainees, the median total contamination scores were 10.0 [IQR 8.25-10.0] and 6.0 [IQR 4.75-9.0] for the experimental group (p = 0.002). For faculty members, the median total contamination scores were 8.5 [IQR 7.5-10.0] for the control group and 5.0 [IQR 4.0-5.0] for the experimental group (p = 0.001).

Individual site rates of contamination, a secondary exploratory endpoint, are in Table 2. Sites with statistically significant reductions in contamination for the experimental group include the reservoir bag (p = 0.002), adjustable pressure limiting (APL) valve (p = 0.003), vital signs monitor or ventilator screen (p<0.001), I.V. stopcock (p = 0.026), medication syringes (p < 0.001) and anesthesia supply cart (p = 0.012). No statistically significant difference in contamination was noted for outside of the aerosol box, anesthesia machine workstation, gown, or gloves.

The distribution of aerosol box cleaning scores, a secondary endpoint, are shown in figure 4.
A statistically significant difference in distribution between the control and experimental group was found ($p = 0.009$). In the experimental group, 36.4% of subjects completely cleaned the aerosol box compared to only 4.5% in the control group ($p = 0.009$, OR = 1.5 [1.08-2.08]).
Discussion

The COVID-19 pandemic has led to a variety of PPE innovations to limit viral exposure to health care workers [1,2]. The aerosol box has been promoted throughout scientific journals, news and social media as an effective method for limiting viral exposure during aerosolizing procedures, yet no high-quality evidence for its use exists. Despite its use, concerns exist regarding practitioner understanding of proper aerosol box use and potential unintended viral contamination associated with improper box use.

Our study is significant for several findings. First, we demonstrated that intraoperative contamination can be decreased with the use of a visual aid as measured as a decrease in the total contamination score. Individual sites with consistent contamination for all subjects included the outside of the aerosol box, the anesthesia workstation and the subjects’ gown and gloves, therefore care must be taken to consistently avoid contamination of these areas. This contamination, particularly of the gown and gloves, could lead to increased intraoperative contamination and potential viral exposure to healthcare workers or subsequent patients. Furthermore, contamination of the anesthesia workstation may provide a reservoir for further contamination throughout an anesthetic or procedure despite proper hand hygiene [25].

Secondly, this study showed that cleaning of an aerosol box can be increased with use of a visual aid. The effectiveness of this visual aid is likely associated with the lack of any pre-existing
instructions accompanying this rapidly developed device as well the visual aid serving as a reminder of infectious potential associated with aerosol box use. In spite of the visual aid, nearly two thirds of aerosol boxes remained contaminated in the experimental group. Of particular note was the remaining contamination at the corners and edges of the box, which suggests that these may be areas to focus on to fully decontaminate the box. The potential for incomplete terminal cleaning of operating rooms exists [26,27] and any amount of contamination may become clinically relevant if viral transfer to a “clean” environment occurs. SARS-CoV-2 has been shown to be stable on plastic and steel surfaces for up to 72 hours [28] and could easily be transmitted between patients or practitioners if intraoperative surfaces or the aerosol box were improperly cleaned.

Finally, and most strikingly, we demonstrated potentially clinically significant contamination of the operating room and aerosol box independent of visual aid use. Several explanations for high rates of intraoperative contamination and contaminated aerosol boxes exist. The aerosol box could potentially be seen as a false sense of security to the subjects which could lead to less vigilance for infection control when compared to intubation without an aerosol box. Studies prior to the COVID-19 pandemic have found intraoperative contamination to be high [25] despite recommendations such as improved intraoperative hand hygiene [29], double gloving for intubation [23], protective devices during intubation [24] and more. Additionally, the aerosol box is an unfamiliar device to most practitioners and the novelty of it may cause changes in practice leading
to increased intraoperative contamination or lack of thorough decontamination. The box’s geometry may also lend to a lack of thorough cleaning as the corners and edges were most often missed by subjects.

Our study adds to the growing number of criticisms associated with aerosol box use. Concerns associated with increased difficulty with airway management, restricted access to the patient for assistants, difficulties with portability in emergencies, the requirement for specialized supplies, potential to damage PPE and potential redirection of aerosols towards the intubator have all been raised [8,15–18]. As a result of the current study, we would add potential for viral contamination to the list of concerns with aerosol boxes. Further investigation into intubation barrier devices’ effectiveness and safety are required.

The greatest limitation of this study is related to the simulation environment. Subjects were told they were in an operating room taking care of a person under investigation for COVID-19, but in reality were in a simulation lab and may not have been as careful as a real life situation. Similarly, the subjects knew they were being observed for the study and the Hawthorne effect must be considered. Although the fluorescent powder used in this study has commonly been used as a marker for viral and bacterial contamination, its use as a simulated SARS-CoV-2 virus has not been proven. One modification to this study could have been to evaluate if the fluorescent marker contamination was spread to the next simulated patient following cleaning, but this was not done
due to time constraints. Subjects had no prior experience using the aerosol box during a simulation or in patient care, but all were aware of the concept through scientific journals, news and social media. Despite this lack of prior experience, we believe this data is generalizable because prior to COVID-19 the aerosol box was not used by any practitioners. However, these findings may be different in a practitioner with more experience using the aerosol box. Finally, numerous barrier devices exist and several modifications to the original design used in this study have been made; it is unclear how the current study’s findings would translate to other aerosol box designs.

We recommend a thorough evaluation of needs for those considering aerosol box use as it may have numerous unintended consequences. If an aerosol box is used, all users should receive at minimum a visual aid describing how to best use and clean the aerosol box. Given the uncertain benefits, our recommendation is to forgo aerosol box use and utilize appropriate PPE with all necessary precautions such as a rapid sequence induction and intubation with a video laryngoscope [1,30]. It is vital that all practitioners, regardless of aerosol box use, stay vigilant during use and cleaning of the operating room.

COVID-19 Aerosol Box Tips

**BOX MAY BE INFECTIOUS SOURCE**
- Hands + arms likely contaminated with use

**USE BOX FOR EXTUBATION**

**USE STANDARD PRECAUTIONS WITH INTUBATION**
- Change gloves after intubation
- Don’t touch clean surface with soiled hands

**CLEAN BOX AFTER USE**
- Frequently change cloths for heavy contamination
- Clean from LEAST to GREATEST area of contamination
- Carefully clean CORNERS of box

*Reported as total score number, not as a number or percent contaminated
